Abstract. The mid-infrared provides a unique view of galaxy stellar populations, sensitive to both the integrated light of old, low-mass stars and to individual dusty mass-losing stars. We present results from an extended Spitzer/IRAC survey of M31 with total lengths of 6.6 and 4.4 degrees along the major and minor axes, respectively. The integrated surface brightness profile proves to be surprisingly difficult to trace in the outskirts of the galaxy, but we can also investigate the disk/halo transition via a star count profile, with careful correction for foreground and background contamination. Our point-source catalog allows us to report on mid-infrared properties of individual objects in the outskirts of M31, via cross-correlation with PAndAS, WISE, and other catalogs.

Keywords. infrared: galaxies, galaxies: individual (M31), galaxies: stellar content

1. Introduction

Getting the full picture of the stellar populations in the nearest large galaxy, M31, poses challenges because of the large angular extent of the galaxy on the sky. The PAndAS project (McConnachie *et al.* 2009) covers a large area around M31 in visible light, but observations at other wavelengths are needed to complete the picture. As seen by the S4G survey, the mid-infrared has the advantages of tracing the integrated light of low-mass stars while being relatively unaffected by interstellar extinction (Querejeta *et al.* 2015). The DUSTiNGS survey demonstrates that mid-infrared observations can also be used to identify mass-losing stars with circumstellar dust (Boyer *et al.* 2015).

2. Observations

With about 40 hours of *Spitzer* observations in the post-cryogenic mission, we extended the IRAC 3.6 and 4.5 μm mapping of M31 presented by Barmby *et al.* (2006) to larger distances along the major and minor axes of the galaxy (Fig. 1). Rafiei Ravandi *et al.* (2016) describes the observations, the challenging process of background subtraction, and construction of a point-source catalog containing over 400000 individual sources. The catalog reaches (Vega) magnitude of ≈ 19 at both 3.6 and 4.5 μm , about 1 magnitude fainter than the tip of the red giant branch luminosity at the distance of M31. Using wide-field/shallow surveys to model the foreground and narrow-field/deep surveys to model the background, we developed a scheme to estimate the probability that a given mid-infrared source belonged to M31. The effects of background subtraction on integrated photometry and the limited overlap between integrated measurements and star counts meant that our measurements of the surface brightness profile were not a substantial improvement over those presented by Courteau *et al.* (2011), which was based on the Barmby *et al.* (2006) data.

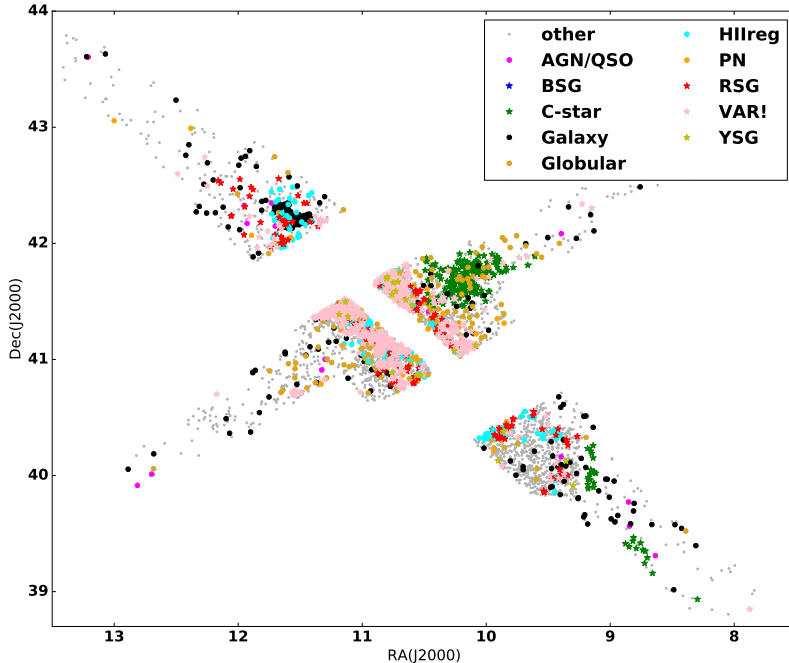

Figure 1. Sky positions of point sources in the outskirts of M31 matched to SIMBAD sources with a tolerance of 1 arcsec. Blank regions along the major and minor axes are locations where crowding was too severe for accurate point-source extraction. The concentration of galaxies in the northeast part of the disc is due to identification in a study of M31 star clusters by the PHAT project (Johnson *et al.* 2012) while the carbon stars to the northwest are from a study of the satellite galaxy NGC 205 by Demers, Battinelli & Letarte (2003).

3. Analysis: mid-infrared point sources in M31

Our extensive point-source catalog allowed for detailed comparisons between the stellar populations as seen in the IRAC 3.6 and 4.5 μm bands and those observed at other wavelengths. Comparing with 2MASS and WISE (Rafiei Ravandi *et al.* 2016, Fig. 6), we find that sources detected only by IRAC and WISE detections are redder and fainter than those detected by all three of IRAC, WISE, and 2MASS. This is consistent with the greater depth and redder response of WISE compared to 2MASS. Comparing with PAndAS (Rafiei Ravandi *et al.* 2016, Fig. 7), we find that the (optically-redder) IRAC+PAndAS detections are more likely to be Galactic foreground dwarfs compared to the PAndAS-only detections; however, the IRAC observations do detect some probable M31 giants.

Both the SIMBAD and NED databases include individual components of nearby galaxies (e.g., stars, star clusters, planetary nebulae, HII regions), although these are not the main focus of either database. We matched the IRAC sources against SIMBAD objects with a distance tolerance of 1 arcsec, with the results shown in Figures 1 and 2. Figure 1 shows that, as expected, the sources categorized as stars or star-related (PNe, HII regions) are strongly concentrated toward the disk of the galaxy, while background galaxies and active galactic nuclei are more uniformly distributed. Globular clusters fall in between these two distributions and are easily detectable in this dataset.

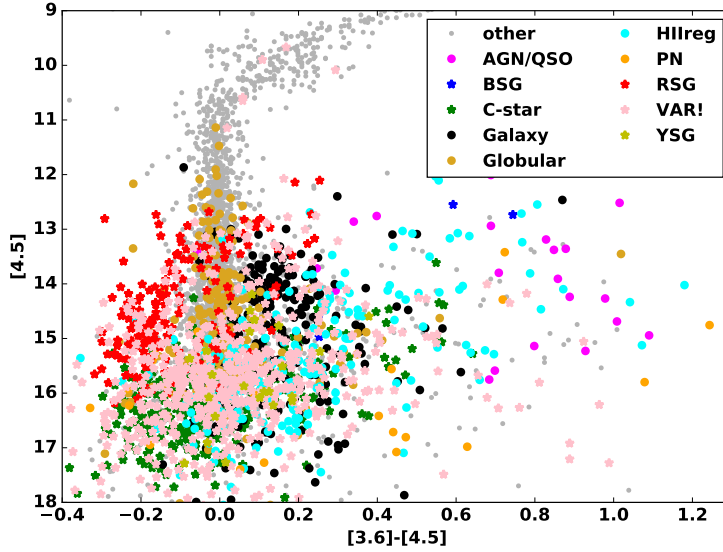

Figure 2. Spitzer/IRAC colour-magnitude diagram showing point sources in the outskirts of M31 matched to SIMBAD sources with a tolerance of 1 arcsec. All magnitudes are in the Vega system; the red colours of objects brighter than $[4.5] \approx 11$ are due to saturation in the $3.6 \mu\text{m}$ band.

Figure 2 shows the colour-magnitude diagram of matched sources. As expected from the results of deep-field extragalactic surveys, the active galactic nuclei and quasars have very red $[3.6] - [4.5]$ colours; background galaxies are mostly found at $[3.6] - [4.5] > 0.1$. Globular clusters have Vega-magnitude colours $[3.6] - [4.5] \approx 0$ (see also Barmby & Jalilian 2012). Individual stars in M31 show a wide range of mid-infrared colours; interestingly, (optically) red supergiants are mostly found at $[3.6] - [4.5] < 0$ while the handful of blue supergiants have $[3.6] - [4.5] > 0.2$, so ‘red’ and ‘blue’ are reversed in the mid-infrared. This is consistent with the results of Britavskiy *et al.* (2015) on similar stars in Local Group dwarf irregulars.
